on your commodore 64 you might need to create a floppy image (if you only have a floppy drive) or you could use the built-in floppy drive as a disk drive. the disk format was of course the gcr format, just like on a 1541. basically the 1541 is a disk drive with disk drives. it just happens to use platter disks. the disk is inserted and the drive spins it up, reads the data and transfers it to the c64. there it is read and processed for checksumming. this was done by using three buffers, one for the data and two for a checksum. the checksum was done on the c64, because the 1541 had more cycles and read and write interrupts to the c64. when the c64 decodes the checksum, it detects a crc check error and informs the 1541. the 1541 interrupts and stops the transfer. the 1541 then checks to see if the data transfer can continue. this is done by interrupting the c64 and waiting for it to read the data. if it reads ok, the transfer continues. this way, you can always retry to a more reliable part of the disk and get some extra speed. the 1541 also has a ton of interrupt handlers and they each all deal with some special case that needs special attention. the interrupt handlers also need to deal with a few quirks of the 1541. for instance, when the 1541 transfers a disk to the c64, the interrupt handler is interrupted by the c64 when it reads the disk header. it isnt done immediately. the main routine reads the disk header, then interrupts itself and starts waiting for the c64 to read the data. this is done because the 1541 transfers the data in blocks. the c64 reads the header and then, if needed, reads the data of the next block. the main routine is interrupted and waits for the c64 to read the data of the next block. this is done to ensure that the main routine can be interrupted as early as possible and that it can keep track of where it is in the transfer.

one of the most important properties of a file system is how quickly it can be scanned or accessed. a real-time file system is one that is able to complete access requests without additional delay. the read-write head of a hard disk moves in a seek-to-read-and-write mode and it can't go back the same way it came. (*1) this was true in the years before disks were magnetized, where the front side was always the same. any developer could have created the first non-magnetic disks by simply flipping them over. they were called "flip disks" and they were very popular. hard drives themselves had to be redesigned. the disk controller had to become aware of which side was the front. this is why the magnetic storage technology association (m.s.t.a.) was founded in the 1980's. they set about creating a standard that would allow non-magnetic disks to be implemented in computers. it was called the "open technology alliance" (o.) and the first standard was formally adopted in 1991. there have been at least two further standards and at the time of this writing the latest is the "flipside-duo" that implements the "front-back-dual" storage scheme. it became the de facto standard for pc and server drives by the time of the b.m. (b.)

standard. this is just one of the problems that could occur. as mentioned, there are other methods to prevent this. the most common method is to write over the entire disk. the data is rewritten to the empty space on the disk and over the entire disk. this method is used on a routine basis and the disk controller can be set to do it automatically on every drive operation. it is also used to make sure that no data is left on the disk that is not meant to be there. otherwise, if you accidentally overwrite data on the disk you will have no way to recover it. shred will do this. the disks also have a method where they are used to store data about the disk itself and some other information. the disk's controller checks to see if the disk is being used and if it is then it will erase all of the data on the disk.
